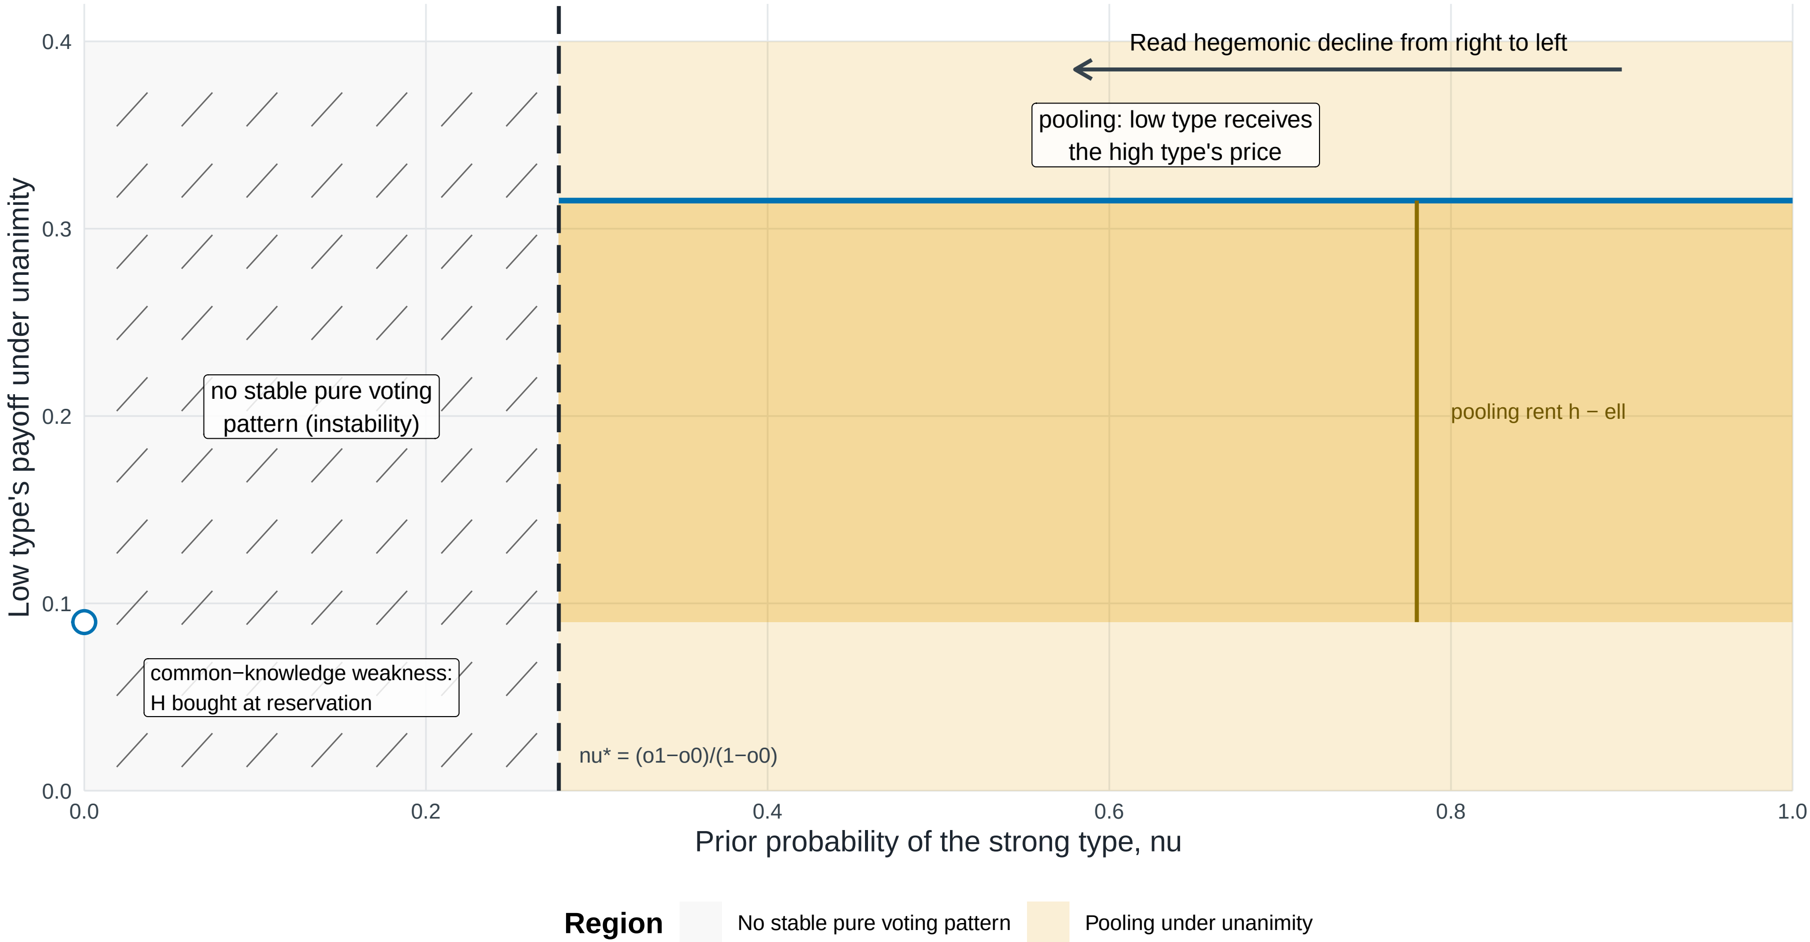
Figure F4. Hegemonic decline moves from pooling through instability to an isolated endpoint

o0 = 0.100; o1 = 0.350; m = 4 weak states; beta = 0.90



The figure should be read from high to low nu. Above nu*, pooling pays the low type h = beta x o1, creating the rent h − ell relative to its reservation price ell = beta x o0. The light orange field identifies the pooling region; the darker band isolates the payoff−relevant rent between ell and h. For 0 < nu <= nu*, the hatched area records the absence of a stable pure voting pattern; nu = 0 is an isolated complete−information endpoint, not an interval, and the low type is bought at reservation. This is a qualitative interpretation analogous to Edgeworth−cycle instability, not a theorem that the game cycles. Note: Model−generated regions; all boundaries closed−form.
